Abstract

To hide a binary pattern in the palette image a steganographic scheme with blind detection is considered. The embedding algorithm uses the Lehmer code by palette color permutations for which the cover image palette is generally required. The found transformation between the palette and RGB images allows to extract the hidden data without any cover work.

1 Introduction

Palette or indexed images are widespread in the Internet and various steganographic techniques have been developed to protect them. Graphic formats store the palette image creating a data set and a palette array which can be used for hiding the information. The modification of data set or palette as LSB-embedding often introduces noticeable artifacts. The possible solutions include sorting palette, parity and adaptive embedding [1] and others [2].

Numerous techniques are based on the fact that reordering the palette colors and reindexing the data set can leave the image visibility unchanged. The GIF-Shuffle steganography program implements this solution for GIF images [3].

The GIF-Shuffle encodes message using the palette color permutations and uses an algorithm that generates permutation according to a given integer. In the same manner SteganoGifPaletteOrder uses permutations of colors in the GIF palette [4]. Together with color images such technique, known as GIF-it-Up, allows to hide information in grayscale GIF images [5].

Encoding by permutation also known as Lehmer code [6] assumes a choice of initial ordering. For instance, the GIF-Shuffle program sorts the palette RGB colors of the GIF using a "natural" order, i.e. every color is assigned to the value $6536R + 256G + B$ and then sorted accordingly. It means that to retrieve the hidden information it needs this "natural" order or in other words

*E-mail: helenkainarova@gmail.com

it needs the cover work. From this point of view the steganographic system used the permutation code would have not blind detection. This is not a fatal restriction. Such "natural" order may be considered as a secrete key. The key can be distributed among the legitimate users via numerous classic cryptographic protocols and via a quantum protocol such as BB84 [7].

In this paper we propose a scheme with blind detection. The reason is that the cover image may be generated from the palette stego image if it will could be transformed into its RGB representation. That is possible thanks to the particular transformation between the palette and the RGB images. The main aim of our paper is to consider this map and to discuss the embedding of a binary pattern using the Lehmer code.

To improve the security level the GIF-Shuffle and the SteganoGifPalette-Order techniques propose encryption. A possible encryption algorithm may be the ICE (Information Concealment Engine) with a 64 bit key [8]. Indeed, to hide binary images a Vernam cipher may be suitable. When the key is implemented by a random binary matrix a one-time pad can be built. This is a perfect encryption if it is used correctly [9]. On practice one-time pad application is limited, it needs storing and distributing a large random key, that is very expansive. However its modern implementation based on the optical beam splitter of random structure may be efficient [10].

The paper is organized as follows: at first the Lehmer code is briefly discussed, then transformations of palette images are considered and finally a steganographic scheme with blind detection is described.

2 Lehmer code

The Lehmer code enumerates permutations by an integer represented in the factorial number system . It allows encoding the binary message by a permutation and it needs an initial permutation called identity.

Positive integer m can be represented with the help of the factorial number system as

$$m = \sum_{k=1}^{n} a_k (k-1)!, \tag{1}$$

where factorial digits $a_k = \lfloor m/(k-1)! \rfloor \mod (k)$ take their value from the set $0, 1, 2, \ldots k-1$, and the floor function $\lfloor x \rfloor$ computes the largest integer less or equal to x. The representation (1) can be considered as a factorial n-digital register, that stores any integer from the range $[0, n!-1]$. For example, six factorial digits of 251 from a_6 to a_1 read

$$251 = (2,0,2,0,1,0)_! = 2 \cdot 5! + 0 \cdot 4! + 2 \cdot 3! + 0 \cdot 2! + 1 \cdot 1! + 0 \cdot 0!. \tag{2}$$

The Lehmer code is one of the ways of encoding permutations using the inversion. Items x_k and x_j of a permutation are called in the inversion if $x_k > x_j$ for

$k < j$. Let t_k be the number of all inversions of x_k, then vector $t = (t_n, t_2, \dots t_1)$ can uniquely describe any permutation of n entries. As there are $n - k$ items to the right from x_k, then x_k creates no more than $n - k$ inversions and t_k can take its value $0, 1, 2 \dots n - k$, where 0 denotes no inversion and $\max t_k = n - k$. For example, assume the permutation of $n = 6$ entries be $P(012345) = 204153$, where 012345 is the identity permutation. Then $\max t = (5, 4, 3, 2, 1, 0)$, where 0 indicates the fact that the item 5 is the last and there are no items on its right. For this case

$$\begin{array}{rcccccc} P(012345) = & 2 & 0 & 4 & 1 & 5 & 3 \\ t = & (2, & 0, & 2, & 0, & 1, & 0), \end{array} \tag{3}$$

where the first item 2 from t indicates that the first item of permutation 2 creates inversions with 0 and 1.

The considered examples (2) and (3) illustrate the one-to-one correspondence between the permutation presented by its inversions and the integer m presented by its factorial digits

$$251 = (2, 0, 2, 0, 1, 0)_! \leftrightarrow 204153.$$

Another example is the permutation of $\max t = (n-1, \dots, 2, 1, 0)$ that refers to full inversion of its entries $P_{inv}(012 \dots n-1) = n-1 \dots 210$

$$n! - 1 = (n-1, \dots, 2, 1, 0)_! \leftrightarrow n-1 \dots 210. \tag{4}$$

The Lehmer code allows to encode any digital images using permutations. For instance, considering a binary image, this is a set of binary digits of an integer m that can be represented in the factorial number system. Figure (1) illustrates first steps. A 41×41 binary image of two colors (red and black) is transformed into an integer m that consists of 503 decimal and 256 factorial digits. Factorial digits are arranged into the 16×16 matrix shown in the Fig. (1) (d).
Then to generate the desired permutation for the given m an identity permutation has to be selected. This fact is important for the palette color embedding techniques based on the color permutation. For this case the identity permutation is given by the cover palette and it is required for detection of hidden data. As result the detection algorithm will use the cover image and will not be blind. However the cover palette can be achieved from a stego image thanks to particular features of the palette color transformation.

3 Transformation between palette and color images

A palette image can be converted into another one so that both images will have the same RGB appearance that can be converted reversibly only to one of them.

From the mathematical point of view a palette or indexed image can be represented by a tensor product $C_{pal} = I \otimes P$, where I is a data set or an index array, and P is a palette that maps the color in RGB model. When index $i \in I$ refers to the palette it takes the color and then there is a transformation $C_{pal} \to C_{rgb}$, where C_{rgb} is an RGB representation of the palette image or its appearance we see on the display.
A common transformation between color and palette images is irreversible. The usual representation has 24 bit for color pixel and 8 bit for palette pixel. A large number of color quantization algorithms allows us to convert a 24-bit color image into a palette image of 8 bit color - $C_{pal}(8)$. Here the entropy is not preserved and this transformation is lossy, however the achieved palette image may look nice.
Let the image $C_{pal}(8)$ have its RGB appearance of 8 bit color $C_{rgb}(8)$. Using the same color quantization algorithms we convert this RGB image back into the palette one. The algorithms are assumed to be deterministic then clear that output is $C_{ind}(8)$. It means that there is the one-to-one correspondence between $C_{rgb}(8)$ and $C_{ind}(8)$:

$$C_{rgb} \rightleftarrows C_{ind}. \tag{5}$$

Indeed, this reversible transformation can not couple all pairs of images and there is a set of palette images for which (5) is not reversible.

Palette images can be transformed from one to another using different approaches. A simultaneous changing of the index and the palette colors may result in a transformation $C_{pal} \to S_{pal}$, where both palette images have the same RGB appearance C_{rgb}. Let C_{pal} and C_{rgb} be coupled by (5). Then clear that the quantization algorithms convert C_{rgb} into C_{pal} instead of S_{pal}. This observation is described by the next mapping

$$C_{rgb} \rightleftarrows C_{pal} \to S_{pal} \to C_{rgb}. \tag{6}$$

Figure (2) illustrates the map given by (6). Here the RGB color image C_{rgb} and the palette image C_{pal} are converted from one to another by Matlab functions `rgb2ind` and `ind2rgb` in accordance with Eq (5). Two palette images are given by its index arrays, grayscale patterns and palettes. The image S_{pal} is a negative of C_{pal}. The negative is achieved by replacing the indexes and the palette colors or the palette rows with $i \to i' = 255 - i$. Being negative patterns both images C_{pal} and S_{pal} have the same RGB representation given by C_{rgb}.

4 Steganographic scheme with blind detection

Two palette images that have the same RGB appearance may be considered as a pair of cover and stego works of a steganographic scheme where the hidden message can be extracted from the stego image.

Two palette images shown in the Fig (2) have the same look and one of them - S_{pal} is achieved from C_{pal} by inversion of its colors and indexes. Using this

approach a message was embedded and it can be established easily. It follows from the Lehmer encoding that the permutation that inverts all n colors has integer $m = n! - 1$ (4). This integer consists of not less than $N = \log_2(n!)$ binary digits and is a message M embedded into the palette. Without loss of generality we will consider M as a binary image. However this image will consist of 1 only and its Shannon entropy $H(M) = 0$. For a palette of $n = 256$ colors $N \geq 1684$ and being accurate up to 3 bits we find that M is a 41×41 matrix of 1 that may look as a black square. It means that embedding the message as a "black square" is a complete inversion of the palette colors.

Fig. (3) illustrates embedding a binary image by the Lehmer code. The 41×41 binary image presented in the Fig. (1) (a) is embedded into the cover work C_{pal} in the Fig. (2) (b). The stego image S_{pal} is shown in the Fig. (3) (b), and is achieved by the found permutation of the palette colors and indexes of C_{pal}. A piece of the permutation is given at the button, in the Fig. (2) (c).

After the message is embedded the stego image S_{pal} can be storied in such graphic formats as GIF and PNG for further use without any lossy transformations. To extract the message from S_{pal} it should be downloaded from GIF or PNG and in accordance to (6) the solution is obtained after executing the following steps:

- palette is extracted from S_{pal} and cover image C_{pal} is generated from C_{rgb} that is the color representation of both the stego and the cover images;
- palette is extracted from C_{pal} that is the identity permutation of colors;
- the hidden message is extracted from the the palettes by Lehmer encoding.

Note that the presented scheme is not secrete from the Kerckhoff's principal point of view because it has no secrete key. A possible solution is to generate a random binary matrix of the size equal to the binary message and combine them, for example, by modular addition. When the matrix is random and is never reused the obtained system (known also as a one-time pad) is unbreakable.
